

Community Detection through Representation learning in Evolving Heterogenous Networks

A Master's Thesis proposal

EGOR DMITRIEV, Utrecht University, The Netherlands

Recent developments in big data and graph representation learning have allowed researchers to make breakthroughs in social network analysis and the identification of communities. While opening a lot of research opportunities, such approaches are highly limited to snapshots of rapidly evolving social networks. This, in fact, is a great simplification of the real-world situation which is always evolving and expanding by the user and/or machine interactions.

Relying on novel research of dynamic graph representation learning, the goal of my thesis project is to build a framework for community detection and representation in dynamic heterogeneous networks. To verify the merit of the proposed framework, it will be evaluated against baselines on static heterogeneous graphs, and analyzed against gathered twitter dataset on covid measures.

1 INTRODUCTION AND BACKGROUND

Social Network Analysis (SNA) is a huge part of the Network Science field and is concerned with the process of investigating social structures that occur in the real-world using Network and Graph Theory. These social structures usually include social media networks [23, 29], economic transaction networks [41, 64, 74], knowledge networks [8, 27], and disease transmission networks [54, 72].

One main issue to address while studying this type of real-world events lies in the identification of meaningful substructures hidden within the overall complex system. The SNA is therefore applied to extract patterns from the data usually in form of information flow, identification of high throughput nodes and paths, and discovery of communities and clusters. In this thesis, we are going to focus on the problem of community discovery.

This thesis proposal is structured as follows: in this section, we are going to introduce basic concepts and challenges of Dynamic Community Detection. In Section 2 a brief literature survey is conducted, identifying the current state of the art and approaches to Dynamic Community Detection. In Section 3 we will describe the problem we are trying to solve as well as formulate the research questions. In Section 4 we will elaborate on our proposed methodology for solving the posed problem and answering the research questions. Finally, in Section 5 the concrete planning for the research project is laid out.

1.1 Community Detection

The problem of partitioning a complex network into *communities* which represent groups of individuals with high interaction density, while individuals from different communities have comparatively low interaction density is known as Community Discovery (CD). CD is a task of fundamental importance within SNA as it discloses deeper properties of networks. It provides insight into networks' internal structure and its organizational principles.

Many useful applications of CD have been studied by researchers including identification of criminal groups [71], social bot detection [37], targeted marketing [55], and public health/disease control [69].

With the explosion of human- and machine-generated data, often collected by social platforms, more datasets are emerging having rich temporal information that can be studied. Most of the CD methods operate only on static networks. Meaning that their temporal dimension is often omitted, which often does not yield a good representation of the real world, where networks constantly evolve. Such networks are often referred to as dynamic networks as their components such as nodes and edges may appear and fade from existence. Accordingly community detection on such dynamic networks is called Dynamic Community Detection (DCD).

DCD algorithms that incorporate additional temporal data are often able to both outperform their counterpart CD algorithms [19, 24, 50, 65], as well as provide additional information about communities for analysis [60]. This additional information comes in form of community events such as (birth, growth, split, merging, and death) or in form of the ability to track the membership of certain individuals over time.

1.2 Challenges in Community Detection

DCD is seen as the hardest problem within Social Network Analysis. The reason for this is mainly because DCD, unlike CD, also involves tracking the found communities over time. This tracking

relies on the consistency of the detected communities, as usually slight changes to the network may cause a different community membership assignment. Not properly accounting for this uncertainty may cause community and result drift [14].

Additionally, the increasing richness of the data is not only limited to temporal data. The real-world data often connects entities of different modalities. This multi-modality occurs through the fact that the entities and relations themselves may be of different types (meta topology-based features). For example users, topics, and documents in a social network (or vehicles and landmarks in a traffic network). More complex networks may include asymmetric relationships, and temporal networks may include appearing, disappearing, or streaming edges/nodes.

Another example of multi-modality in networks comes in the form of node and relation features (content-based features). These features may come in the form of structured (numerical, categorical, or vector data) or unstructured data such as images and text. It is of high importance to explore this multi-modal data as it may not always be possible to explain the formation of communities using network structural information alone.

Finally, a more systematic issue is that there is no common definition for a community structure. Within networks, it is usually described in terms of membership assignment, while in more content-based settings communities are described in terms of modeled topics (that usually represent interest areas) or distributions over latent similarity space. Both definitions have their shortcomings as they often fail to account for more complex community structures (overlapping and hierarchical communities) and non-linearity of structures often found in the real world.

The task of community detection is often compared to clustering and graph clustering, which not always may be a fair comparison as a main focus point in many CD algorithms is the fact that the amount of communities is unknown a priori. Communities are never planted in the real world and the algorithms should detect them in an unsupervised manner.

2 LITERATURE REVIEW

The problem of dynamic community detection was noticed quite early on within the SNA community and a considerable amount of research has been made in order to provide a comprehensive analysis [14, 66, 75]. While the said research was mostly focused on the discovery of communities using topologically-based features and node connectivity, the covered methods did research the limitations and challenges posed by a temporal context.

In recent years, significant developments have been made in the space of deep learning. Mainly in the development of new deep learning methods capable of learning graph-structured data [9, 31, 39] which is fundamental for SNA. Because of this, various problems within the field have been revisited, including community detection problems. The approaches have been expanded by incorporation of more complex features, solving the problems concerning multi-modality, and the introduction of unsupervised learning.

Despite this resurgence, the DCD problem has received little attention. Though a few efforts have been made to incorporate the deep learning methods by introducing content-based similarity [11, 19, 34], the definition of unified constraints for end-to-end learning [10, 35, 52, 85], and usage of graph representation-based CD algorithms [49, 81] within a temporal context, the current state of the art leaves room for improvement.

We structure the literature as follows: first, we describe the various interpretations of the Community Structure in Section 2.1. Next, we explore various approaches and techniques related to Graph

Representation Learning in Section 2.2. Then, we provide an overview of the current state-of-the-art approaches for Community Detection and Dynamic Community Detection tasks in Section 2.3 and Section 2.4. Finally, we discuss the ways to evaluate the said algorithms in Section 2.5 and the datasets available in Section 2.6.

2.1 Community Structures

The goal of this section is to introduce fundamental structures for the Dynamic Community Detection task. We do this by combining various definitions used in the relevant literature as well as establishing the purpose for these structures, before proceeding into approaches for detecting communities in the following sections.

2.1.1 Communities

Communities in real-world networks can be of different kinds: disjoint (students belonging to different educational institutions), overlapping (person having membership in different social groups) and hierarchical (components of a car). One of the main reasons behind the complexity of CD is that there is not one unique definition what a community actually is.

The *link-based* (also referred to as classic) community detection methods intuitively describe communities as groups of nodes within a graph, such that the intra-group connections are denser than the inter-group ones. This definition is primarily based on the *homophily* principle, which refers to the assumption that similar individuals are those that are densely connected together. Therefore, these kind of methods look for sub-graph structures such as cliques and components that identify connectedness within the graph structure to represent the communities.

Unfortunately, in most cases link-based methods fall short to identify communities of similar individuals. This is mainly due to two facts: (i) many similar individuals in a social network are not explicitly connected together, (ii) an explicit connection does not necessarily indicate similarity, but can be explained by sociological processes such as conformity, friendship or kinship [17, 19].

A more general definition is introduced in [?] to create an underlying concept generalizing all variants found in the literature (Definition 1). In link-based methods, a direct connection is considered as a particular and very important kind of action, while newer methods also consider content or interest overlap.

DEFINITION 1 (COMMUNITY). *A community in a complex network is a set of entities that share some closely correlated sets of actions with the other entities of the community.*

2.1.2 Dynamic Communities

Similar to how communities can be found in static networks, dynamic communities extend this definition by utilizing the temporal dimension to define their life cycle/evolution over a dynamic network. A dynamic community is characterized by a collection of communities and a set of transformations on these communities over time.

This persistence of communities across time subjected to progressive changes is an important problem to tackle. Though, as noted by [66] the problem can be compared to the famous “the ship of Theseus” paradox. Because (verbatim), *deciding if an element composed of several entities at a given instant is the same or not as another one composed of some—or even none—of such entities at a later point in time is necessarily arbitrary and cannot be answered unambiguously.*

Most of the works agree on two atomic transformations on the communities, including node/edge appearance and vanishing. In other works such as [4, 11, 60] authors define a more high-level set of transformations (also referred to as events) built on top of the atomic ones. These transformations more interesting for analytical purposes and include:

- Birth, when a new community emerges at a given time.
- Death, when a community disappears. All nodes belonging to this community lose their membership.
- Growth, when a community acquires some new members (nodes).
- Contraction, when a community loses some of its members.
- Merging, when several communities merge to form a new community.
- Splitting, when a community is divided into several new ones.
- Resurgence, when a community disappears for a period and reappears.

These events/transformations are often not explicitly used during the definition and/or representation of dynamic communities. Nevertheless, most of the methods covered in the following sections do define a way in their algorithm to extract such events from the resulting data.

Finally, it is important to note that dynamic networks can differ in representation. They can be represented as either a time series of static networks (also referred to as snapshots) or as a real-time stream of edges (referred to as temporal networks). Within the global context of dynamic community detection, they can be seen as equivalent as the conversion between the two representations can be done in a lossless way. The latter, temporal networks are often used to handle incremental changes to the graph and are most commonly applied within real-time community detection settings.

2.2 Graph Representation Learning

The representation-based approaches stem from the field of computational linguistics which relies heavily on the notion of *distributional semantics* stating that words occurring in similar contexts are semantically similar. Therefore the word representations are learned as dense low-dimensional representation vectors (embeddings) of a word in a latent similarity space by predicting words based on their context or vice versa [53, 62]. Using the learned representations similarity, clustering and other analytical metrics can be computed.

The success of these representation learning approaches has spread much farther than just linguistics as similar ideas are also applied to other fields including graph representation learning. Methods such as deepwalk [63], LINE [76], and node2vec [26] use random walks to sample the neighborhood/context in a graph (analogous to sentences in linguistic methods) and output vector representations (embeddings) that maximize the likelihood of preserving the topological structure of the nodes within the graph.

Whereas previously the structural information features of graph entities had to be hand-engineered, these new approaches are data-driven, save a lot of time labeling the data, and yield superior feature/representation vectors. The methods can be trained to optimize for *homophily* on label prediction or in an unsupervised manner on link prediction tasks.

Newer approaches introduce the possibility for the fusion of different data types. GraphSAGE [30] and Author2Vec [89] introduce a methodology to use node and edge features during the representation learning process. Other approaches explore ways to leverage heterogeneous information present within the network by using *metapath* based random walks (path defined by a series of node/link types) [18] or by representing and learning relations as translations within

the embedding space [7]. In Nguyen et al. [59] the authors introduce a way to encode temporal information by adding chronological order constraints to various random walk algorithms. Other relevant advancements within the field include Graph Convolutional Networks (GCN) [40] and (Variational) Graph Auto-Encoders (GAE) [38] which present more effective ways to summarize and represent larger topological neighborhoods or whole networks.

2.3 Link-based Approaches

Link-based approaches to (Dynamic) Community Detection rely on connection strength to find communities within the network. The main criteria for communities are the assumed property that intra-group connections are denser than inter-group ones. The networks are partitioned in such a way, that optimizes for a defined measure characterizing this property.

We start this section by covering the fundamentals of link-based community detection by introducing commonly used community quality measures and algorithms for optimizing them. Next, we introduce the link-based DCD problem and the unique challenges that arise as opposed to CD. Then we proceed to cover the current state of the art by describing the related works, their solutions to the said challenges, and possible extensions to the problem.

2.3.1 Community Detection

Different metrics exist quantifying the characteristic of *homophily* over edge strength. The most common metric is Modularity which measures the strength of the division of a network into modules (communities). Its popularity stems from the fact that it is bounded and cheap to compute, though it has other problems such as resolution limit (making detecting smaller communities difficult). Other metrics that can be found in the literature include but are not limited to:

- Conductance: the percentage of edges that cross the cluster border
- Expansion: the number of edges that cross the community border
- Internal Density: the ratio of edges within the cluster with respect to all possible edges
- Cut Ratio and Normalized Cut: the fraction of all possible edges leaving the cluster
- Maximum/Average ODF (out-degree fraction): the maximum/average fraction of nodes' edges crossing the cluster border

Modularity. Modularity directly measures the density of links inside a graph and is therefore computed on communities (sets of nodes) individually by weighing edges based on community similarity (or exact matching). Calculation of modularity is done by aggregating for each community r and for each pair of nodes vw the difference between the expected connectivity $\frac{k_v k_w}{2m}$ (amount of edges between the nodes) and the actual connectivity A_{vw} (existence of an edge) given their degrees (k_v and k_w). The final result represents the delta connectivity difference by how much the given graph exceeds a random graph as expected connectivity is determined by a random rewiring graph. Because intra-community pairs are weighted lower than inter-community pairs the score can vary. See Eq. 1 where S_{vr} indicates membership of node v for community r and m represents the total edge count.

$$Q = \frac{1}{2m} \sum_{vw} \sum_r \left[\overbrace{A_{vw}}^{\text{Connectivity}} - \underbrace{\frac{k_v k_w}{2m}}_{\text{Expected Connectivity}} \right] \overbrace{S_{vr} S_{wr}}^{\text{Community Similarity}} \quad (1)$$

Louvain Method. Finding an optimal partition of a graph into communities is an NP-hard problem. This is because, while calculating the modularity score can be done in loglinear time, all possible node to community assignments still have to be considered. Therefore heuristic-based methods such as the Louvain method are usually used.

Louvain method [6] is a heuristic-based hierarchical clustering algorithm. It starts by assigning each node in the graph to its own community. Then it merges these communities by checking for each node the change in modularity score produced by assigning it to a neighbor community (based on the existence of a connection). Once the optimal merges are performed, the resulting communities are grouped into single nodes and the process is repeated.

Since modularity changes can be computed incrementally, the complexity of this method is $O(n \log n)$. Additionally, due to the flexibility of the modularity measure, it allows detecting communities in graphs with weighted edges.

Label Propagation algorithm. Another way to sidestep the complexity issue is using the Label Propagation algorithm as it uses the network structure directly to define partitions and doesn't require any priors (quality metrics). The intuition for the Label Propagation algorithm is as follows: When propagating a label through connections in the network, a single label quickly becomes dominant within a group of densely connected nodes, but these labels usually have trouble crossing sparsely connected regions.

The algorithm starts by assigning each node their own label. After that, for each iteration, each node updates its label to the majority label among its neighbors where ties are broken deterministically. The algorithm stops after a fixed amount of iterations or once it has converged. An important feature of this algorithm is that a preliminary solution can be assigned before each run, therefore only updating existing membership assignments.

2.3.2 Dynamic Community Detection

Dynamic Community Detection can be seen as an extension to community detection by the addition of the Community Tracking task. Tracking relies on the coherency and stability of found communities to define their evolution through time. The said properties can not be taken for granted and introduce new challenges when designing DCD methods. The main issue is in fact that they are competitive with each other causing a trade-off between community coherency/quality and community temporal stability.

Various strategies dealing with this trade-off are categorized by Rossetti and Cazabet [66] and Dakiche et al. [14] where authors reach a consensus over three main groups. In the following sections, we briefly introduce these strategies and describe the current state of the art in similar order.

Independent Community Detection and Matching. Also referred to as the two-stage approach. Works by splitting the DCD task into two stages. The first stage applies CD directly to every snapshot of the network. Followed by the second stage matching the detected communities between the subsequent snapshots.

The advantages of this approach include the fact that it allows for use of mostly unmodified CD algorithms for the first step and that it is highly parallelizable as both detection and matching steps can be applied to each snapshot independently. The main disadvantage is the instability of underlying CD algorithms which may disrupt the community matching process. Many CD methods may give drastically different results in response to slight changes in the network. During the

matching, it becomes difficult to distinguish between this algorithm instability and the evolution of the network.

In Wang et al. [84] the authors circumvent this instability issue by looking at the most stable part of the communities, namely core/leader nodes. In their research, they observe that in various datasets most of the nodes change dramatically while only a small portion of the network persists stably. To exploit this feature, the algorithm CommTracker is introduced which first detects the said core nodes, and then defines rules to both extract communities as well as their evolutionary events. The community members are assigned based on their connectivity relative to core nodes.

Rossetti [65] proposes a way to detect overlapping communities in dynamic networks. A more robust two-phase community detection method (ANGEL) is proposed to ensure the stability of the found communities. The first phase extracts and aggregates local communities by applying Label Propagation on the Ego-Graph (graph excluding a single node) for each node in network. The found communities are biased due to their partial view of the network and are merged in the second step based on their overlap yielding more stable communities with the possibility of overlap. During the matching for each snapshot, a step forward and backward in time is considered where community splits and merges are detected by reusing the matching criteria of the second phase of the CD step.

Dependent Community Detection. Dependent Community Detection strategy works by detecting communities in each snapshot based on the communities found in the previous snapshots. This approach introduces temporal smoothness because the previous solution is reused making the matching process obsolete. Though as part of the described trade-off it can impact the long-term coherence of the dynamic communities. Mainly, because each step introduces a certain amount of error into the results (community drift) which may get amplified within further iterations (error accumulation). Another disadvantage is the fact that the strategy has limited possibilities of parallelization due to its dependent nature.

To lessen the complexity of continuous re-detection of the communities some algorithms process the changes incrementally by limiting the change to a local neighborhood. While this approach has many benefits, it is important to note that these algorithms face a problem where only applying local changes can cause communities to drift toward invalid ones in a global context.

He and Chen [32] introduces an efficient algorithm by modifying the Louvain method. Based on the observation that between consecutive timesteps only a fraction of connections changes and do not affect communities dramatically, they argue that if all community nodes remain unchanged, the community also remains unchanged. With this in mind, they make a distinction between two types of nodes, ones that change the connection in a snapshot transition and ones that do not. The former have to be recomputed, while the latter maintain their community label. The nodes that maintain their community are merged into community nodes with edges to other community nodes and changed nodes weighted proportionally to their real connectivity (amount of edges when ungrouped). This simplified graph is passed to the Louvain method algorithm for community detection. By reusing the community assignments temporal smoothness is maintained and due to the incremental nature of this algorithm, the overall complexity remains low.

Guo et al. [28] envision the target network as an adaptive dynamical system, where each node interacts with its neighbors. The interaction will change the distances among nodes, while the distances will affect the interactions. The intuition is that nodes sharing the same community move together, and the nodes in different communities keep far away from each other. This is modeled by defining the so-called Attractor algorithm, which consists of three interaction patterns that

describe how node connection strength is influenced by neighboring nodes. The edge weights are initialized using Jaccard distance and the propagation is run until convergence. The communities can be extracted by thresholding on edge weight/distance. Thereafter, all changes are treated as network disturbances. The disturbance can be limited to a certain area using a disturbance factor which defines a bound on the possible propagation.

More recently the Yin et al. [95] has proposed an evolutionary algorithm by looking at the DCD from an Evolutionary Clustering Perspective. They detect community structure at the current time under the guidance of one obtained immediately in the past by simultaneously optimizing for community quality score (modularity) and community similarity between subsequent time steps (NMI). In the methodology, a way is proposed to encode a graph efficiently into a genetic sequence. Additionally, new mutation and crossover operators are proposed which maximize either of the two objectives. By using a local search algorithm, building a diverse initial population, and selecting for dominant candidates the communities maximizing both objectives are obtained.

Simultaneous community detection. The final strategy we consider sidesteps the matching issue by considering all snapshots of the dynamic network at once. This is done by flattening the network in the temporal dimension and coupling edges between the same nodes at different timesteps. These approaches usually don't suffer from instability or community drift. The disadvantages include that the standard principle of a unique partition for each time step can't be applied, as only the combined network is used, therefore limiting the number of possible algorithms. Handling real-time changes to the graph are also usually not considered.

Mucha et al. [57] adopt a simple yet powerful solution to this problem by connecting identical nodes between different time steps within the unified network. On this network, they apply a modified Louvain method algorithm to extract the communities whose members can be split over different timesteps.

Ghasemian et al. [21] apply stochastic block model-based approach. They make a distinction between two edge types: (i) spatial edges (edges between neighbors) and (ii) temporal edges (edges between nodes in subsequent timesteps). Using this distinction, they define a Belief Propagation equation to learn marginal probabilities of node labels over time. Additionally in their research, they introduce a way to derive a limit to the detectability of communities. This is, because some communities may not be detectable as their probability nears that of random chance.

2.4 Representation-based Approaches

The main difference between Representation-based approaches and link-based approaches is the fact that they usually don't directly model the network based on connections. Instead, they learn an intermediate representation of the graph or its components to which CD detection can be applied to. While also relying on the idea of *homophily*, most methods define additional objectives to improve community quality.

The main reasoning for this is the fact that real-world networks are non-linear, meaning that there may be no connections when they make sense and vice versa [85]. By using deep neural networks to learn these embeddings one can address such non-linearity as they are in general very robust against noise. Other notable benefits to using representation-based approaches include the fact that they compress the data efficiently as real-world networks are very sparse. They can also represent multi-modal features, network (meta) structure, and temporal dimension by defining them all in a compatible similarity space or learning mappings to this space. Finally, representations are naturally easy to compute similarity on.

In this section, we describe representation-based approaches by covering both CD and DCD approaches. To provide a more cohesive overview of the methods, we group them by their innovations instead.

2.4.1 Affiliation Graph Models

While arguably not being representational by itself, Affiliation Graph Network (AGM) model introduced in Yang and Leskovec [92] is very influential within the deep learning/representation learning CD field.

The AGM models a network as a bipartite graph with communities as first-class citizens and is represented by the following equation $B(V, C, M, \{p_c\})$, where V represents nodes, C set of communities, M node-community memberships and $\{p_c\}$ model parameters (a single probability p_c per community). It can model non-overlapping, overlapping, and hierarchical communities by defining rules on membership sets in M . AGM can be used in both generative and discriminative settings.

The generative scenario works as follows: Given an AGM $F(V, C, M, p_c)$, generate links between each pair of nodes exceeding a baseline probability p . This is done by considering that, according to AGM, each pair of nodes in community C_i is connected with a probability p_{c_i} . Therefore, the probability of two nodes having a connection is proportional to the number of communities they share (which can be derived from the model).

The discriminative scenario is defined as: Given a graph G , find a model $F(V, C, M, p_c)$ that may have generated it. By assuming that the graph was generated using an AGM, the parameters M , number of communities $|C|$ and $\{p_c\}$ have to be found. Process for finding such a model to the graph involves max likelihood fitting. AGM is relaxed to have membership strengths F_{uC} , which helps to define the probability of nodes u and v connecting through community C as $P_C(u, v)$, and by themselves $P(u, v)$ (by marginalizing over communities). Using this, a probability $P(G|F)$ can be constructed quantifying how well the model fits the data. Finally, gradient ascent can be applied to optimize for the model's parameters.

2.4.2 Graph Reinforcement

The first class of methods we consider are Graph Reinforcement methods. These methods use representation-based learning techniques to enhance the graph by adding valuable edges or reducing the noise by removing noisy connections. This is usually done by training a model on a link-prediction task. A notable benefit of this approach is that other well-known CD methods can be used on the enhanced graph afterward.

Kang et al. [36] present a pre-processing method for strengthening the community structure of a graph by adding non-existing predicted intra-community edges and deleting existing predicted inter-community edges. Their strategy is to learn topological embedding using a graph representation learning algorithm (node2vec) based on the existing link prediction task. The similarity is computed between different node pairs and put into buckets. Then with the assumption of *homophily* the buckets with a higher value can be considered holding intra-community while buckets with lower inter-community connections. Right buckets are picked from both extremes to create or delete edges. The preemptive CD is done to greedily guide pair-wise similarity computation and avoid a high complexity. Once the reinforced graph is constructed, already existing CD algorithms can be applied.

Jia et al. [35] solves the issue of detecting overlapping communities by proposing the CommunityGAN algorithm which jointly optimizes for node and community representations. First, they define a method for efficient motif (in their case clique) sampling from the graph (true/clique, and false/vertex subset). Then, they define a GAN based structure for learning representational vectors where the generator G tries to learn $p_{true}(m|v_c)$ as preference distribution of motifs to generate most likely vertex subsets most likely to be real motifs. Discriminator D tries to learn the probability of a vertex subset being a real motif, therefore creating a minimax game of progressively optimizing embeddings to be able to encode rich information about network topology.

Both components (G and D) are implemented as a modified relaxed AGM model with a more general definition to be able to handle the motif generation (rather than edge generation). The probability of a set of vertices being a motif is defined in terms of their probability being a motif through a community, therefore making them community-aware as they now represent the affiliation weight between a vertex and a community. The number of communities is chosen by training and testing part of data on link prediction task.

2.4.3 Multi-objective optimization

Another subject where representation-based approaches excel is multi-objective optimization. Usually, a combined objective is defined in terms of a community quality, temporal consistency, or homophily measure. These measures in turn use the proximity between the representation to be able to back-propagate the combined error and optimize the representation (function) directly.

In Rozenberczki et al. [68] authors propose a method that learns cluster centers along with node embeddings. They define an objective function as a combination of three terms: normalization term (ensures embeddings are centered at the origin), proximity term (forces nodes with similar neighborhoods to be embedded close), cluster quality term (forces nodes to be close to their nearest cluster). Additionally, a “social network cost” term is added as a regularizer to optimize for proximity between nodes within the same cluster. During training, the clustering coefficient is annealed to ensure convergence and negative sampling is employed to avoid large softmax costs.

Yang et al. [90] propose a similar idea of combining embedding and clustering tasks and solving them in an end-to-end manner. In their work, they employ a Deep Denoise Autoencoder (DAE) to learn topological information of the network by optimizing for reconstruction loss. To learn cluster/community centers they define GRACE cluster module which first computes soft cluster assignment matrix Q by utilizing the embeddings and cluster centers which contain probabilities q_{ik} of node i belonging to cluster k . The clustering loss is defined as (Kullback Leibler) KL-divergence between the soft clustering Q and auxiliary target distribution P which is computed by squaring and normalizing the soft assignments to reinforce more confident clustering results while preventing the formation of excessively large clusters. Both embeddings and clustering are optimized alternatively until convergence.

Ma et al. [52] proposed a novel approach to constructing community-aware dynamic network embeddings by leveraging multi-objective optimization and extending it into a temporal dimension. They adopt a Graph Autoencoder structure which works by encoding the full graph into a lower-dimensional structure and decoding it again into a graph. Assuming a well-tuned autoencoder, this allows authors to encode the input network (and its nodes) into a more efficient representation vectors which characterize the network well.

The objective function they use is defined by three terms: the reconstruction error term minimizing the distance between the ground-truth and the autoencoder output, local structure/homophily

preservation term minimizing first- and second-order proximity between connected nodes, and the community evolution preservation term maximizing temporal smoothness of communities at different granularity levels given their representation as an aggregation of their members.

The initial community assignment is generated using the Louvain method for high-level communities and using K-means for fine-grained communities given a max community size parameter w . After that, embeddings at each snapshot are optimized by employing a dependent community detection-like strategy.

Wang et al. [85] employs a similar strategy for DCD detection by utilizing the Graph Autoencoder architecture. Authors add an additional community score term to the objective function, therefore also minimizing the distance between nodes in the same community. At last, K-means is run on the representational vectors to detect communities at different timesteps while reusing the outputs from the previous step.

2.4.4 Multi-modal community detection

Another way to improve community quality is by incorporating multi-modal features. These can come in the form of node attributes, content-based or meta-topological data. These representations are incorporated into learned embedding vectors either by direct learning, incorporating them into the objective function, or use of pre-trained models.

In Fani et al. [19] the authors describe their method for identifying user communities through multi-modal feature learning. First user embeddings are learned based on their temporal content similarity by looking at topics of interest. Per-user, a heat map is constructed measuring the user's interest over time and topic axes. By considering users like-minded if their heat maps overlap enough they train low-dimensional content embeddings spanning this user similarity space. Next, they use random walk-based GNN methods to learn topological similarity embeddings for network nodes. Finally, they modify the graph by setting edge weights proportionally to node proximity in this combined embeddings space. After that, the Louvain method is applied to extract these time and content-aware communities.

2.5 Evaluation

In the previous section, we have described the different variations of community structure definitions as well as the approaches used for detecting communities. In this section, we will cover how the found dynamic community structures can be evaluated in a more general setting to allow a comparison of different approaches. Dynamic community detection problems can be seen as a combination of two tasks, matching and tracking. Due to the large difference between the two tasks, the evaluation is usually conducted separately for each of the tasks.

In the following sections, we cover both of the evaluation methods for both tasks by classifying approaches used in the literature in three classes, namely, annotated, metric-based, and task-specific.

2.5.1 Annotated

Evaluation of detected (dynamic) communities becomes much easier when the *ground-truth communities* are provided. The evaluation is then done by comparing the difference between the produced communities and the effective ones. To perform this comparison, the information theory-based metric Normalized Mutual Information (NMI) is used which converts community sets to bit-strings and quantifies the “amount of information” that can be obtained about one community by observing the other [46].

A possible drawback of this measure is that its complexity is quadratic in terms of identified communities. In [67] alternative measure (NF1) with linear complexity is introduced which similarly to the F1 score uses the trade-off between precision and recall (of the average of harmonic means) of the matched communities. In the follow-up work [65] the authors describe a way to apply this measure within the context of DCD by calculating this score for all the snapshots and aggregating the results into one single measure.

Aside from NMI other measures are employed such as Jaccard Coefficient, Accuracy and Rand-Index measuring community overlap [51, 56, 90], Overlapping-NMI [94] and Omega-Index measuring is the accuracy on estimating the number of communities that each pair of nodes shares [92],

In the real world, there are usually no ground-truth communities. Therefore this approach is usually applied on synthetic datasets where the communities and their dynamicity is sampled from a distribution. An alternative approach some papers take is by defining ground-truth communities using the metadata and node attributes present within the datasets. Some datasets may include annotated communities, but this is not common within DCD datasets.

2.5.2 Metric based

Another way to evaluate and compare different CD algorithms without knowing ground-truth communities is using a quality function.

Network-based metrics. The first group of measures we consider operates directly on the network structure. They are most commonly used to evaluate link-based methods as their results are network partitioning sets. Modularity is the most widely used measure [58, 73], since it measures the strength of division of a network into modules. Networks with high modularity have dense connections between the nodes within the modules and sparse connections between nodes in different modules. Other measures are used as well including:

- **Conductance:** the percentage of edges that cross the cluster border
- **Expansion:** the number of edges that cross the community border
- **Internal Density:** the ratio of edges within the cluster with respect to all possible edges
- **Cut Ratio and Normalized Cut:** the fraction of all possible edges leaving the cluster
- **Maximum/Average ODF** (out-degree fraction): the maximum/average fraction of nodes' edges crossing the cluster border
- **Triangle Participation Ratio TPR:** measures fraction of triads within the community. A higher TPR indicates a denser community structure

Proximity-based measures. Proximity-based measures are often used to evaluate clustering tasks but are also often employed for representation-based CD methods since there is a large overlap in their methodology. Additionally, representation-based approaches have the benefit of being able to quantify both entities and communities as a d-dimensional vector enabling a more direct comparison of the two [81]. The most common measures include:

- **Silhouette Coefficient:** is defined as $S(i) = \frac{b(i) - a(i)}{\max\{a(i), b(i)\}}$ where $a(i)$ defines the mean distance from node i to other nodes in the same cluster while $b(i)$ is mean distance to any node not in the same cluster. It measures cohesion of a cluster/community and indicates how well a node is matched to its own cluster.
- **Davies-Bouldin Index:** is the ratio of the sum of the average distance to the distance between the centers of mass of the two clusters. In other words, it is defined as a ratio of within-cluster, to the between cluster separation. The index is defined as an average over

all the found clusters and is therefore also a good measure to deciding how many clusters should be used.

- **Calinski-Harabasz Index:** is the ratio of the between-cluster to the within-cluster variance. Therefore it measures both cohesion (how well its members fit the cluster) as well as compares it to other clusters (separation).

Stability-based measures. To evaluate temporal stability and consistency of the node and community structures, measures based on temporal smoothness are proposed in Ma et al. [52]. These measures compare the evolution rate of network structures against the evolution rate of the whole network given node embeddings between two consecutive snapshots. The intuition is that rapidly evolving structures relative to the global evolution rate are temporally unstable and thus of low quality. Metrics proposed include:

- **Network Stability:** Is defined as Eq. 2 and evaluates the evolution ratio of the low-dimensional node representations to the network representations between snapshots at a -th time stamp.
- **Community Stability:** Is defined as Eq. 3 and computes stability of communities in dynamic networks on the embedded low-dimensional representations. It is represented as evolution ratio of the low-dimensional community representations to the network representations between snapshots at a -th time stamp.

$$p_s^a = \frac{\left(\|H^{a+1} - H^a\|_2^2 \right) / \|H^a\|_2^2}{\left(\|A^{a+1} - A^a\|_2^2 \right) / \|A^a\|_2^2} \quad (2)$$

$$p_c^a = \sum_{k=1}^q \left(\frac{\left(\|H_{c_k}^{a+1} - H_{c_k}^a\|_2^2 \right) / \|H_{c_k}^a\|_2^2}{\left(\|A_{c_k}^{a+1} - A_{c_k}^a\|_2^2 \right) / \|A_{c_k}^a\|_2^2} \right) / q \quad (3)$$

Where H_i^a and $H_{c_k}^a$ represent the embedding vector for a node i and a community k at a -th timestamp respectively. Similarly separate node and community based adjacency matrices are defined as A^a and $A_{c_k}^a$. Therefore, in this case $\|H_{c_k}^{a+1} - H_{c_k}^a\|_2^2$ represents the normalized euclidean distance between the two clusters while $\|A_{c_k}^{a+1} - A_{c_k}^a\|_2^2$ represents the normalized euclidean distance between the adjacency matrices of the two clusters. For network stability no such grouping is done and evaluation is performed on node-based (global) representation and adjacency matrices.

2.5.3 Task specific

In [61] the authors criticize annotation and metric-based CD evaluation approaches by proving that they introduce severe theoretical and practical problems. For one, they prove the no-free lunch theorem for CD, ie. they prove that algorithmic biases that improve performance on one class of networks must reduce performance on others. Therefore, there can be no algorithm that is optimal for all possible community detection tasks, as the quality of communities may differ by the optimized metrics. Additionally, they demonstrate that when a CD algorithm fails, the poor performance is indistinguishable from any of the three alternative possibilities: (i) the metadata is irrelevant to the network structure, (ii) the metadata and communities capture different aspects of network structure, (iii) the network itself lacks structure. Therefore, which community is optimal should depend on its subsequent use cases and not a single measure.

To address this issue, it is common to evaluate the algorithm on both earlier described approaches as auxiliary tasks. The general sentiment behind it is, that communities have better quality if they improve an underlying application. In the following sections, we describe a few commonly used auxiliary tasks in literature.

Link-prediction. A common way to evaluate the quality of extracted node embeddings within Graph Representation learning is using the link-prediction task. As link-prediction can be done in an unsupervised manner, it does not require additional labeling for evaluation. The edge set of the input network is split into a train set on which the model is trained, and a test set on which is used to compare the predicted links against. When using node representation learning, the predictions are defined by proximity between the nodes and a threshold. To quantify the quality of the results classification metrics are usually employed such as accuracy, precision, recall, and f-score.

In the context of CD and DCD, the link prediction is modified to measure the predicting capability of the community embeddings. Fani et al. [19] defines a user prediction task to predict which users posted a certain news article at a certain time. Their methodology is, given a news item at time t , find the closest community to the article in representational similarity space. All members of the given community are seen as predicted users over which the classification metrics are calculated. Similarly, Ma et al. [52] modify the task by predicting whether the edges will still exist within the next timestamp to also quantify the temporal prediction capability of the trained embeddings.

Recommendation Tasks. Another way the quality of node representations can be evaluated is by using recommendation tasks. Here the idea is, instead of predicting a single item like in link-prediction, to rank the items based on their recommendation confidence. Using the ranked list, standard information retrieval metrics such as precision at rank, mean reciprocal rank, and success at rank k can be computed. This approach is applied to CD [19, 34, 68] by ranking recommendations per community instead of on an individual basis. Communities with higher scores therefore would indicate high similarity between their members.

2.6 Datasets

In this section, we curate popular datasets used in literature for CD and DCD tasks. First, we discuss methods for generating synthetic datasets containing ground-truth communities. We conclude this section with an overview of real-world dynamic networks.

2.6.1 Synthetic Datasets

Synthetic datasets are datasets generated by specific models using manually designed rules. These datasets are generated with communities in mind and therefore most of the time contain ground-truth communities which can be used for the evaluation of CD algorithms. In this section, we describe a selection of popular synthetic dataset generation techniques.

The most common benchmark dataset was introduced in Lancichinetti et al. [45]. Their method for generating a network creates communities and their nodes with size and degree drawn from a power-law distribution. Thereafter, node edge rewiring is applied to enforce a mixture parameter μ which determines the ratio of in- to between-community connections. In follow-up [44] the authors extend their method to work for overlapping communities.

In Greene et al. [25] the authors modify the Lancichinetti et al. [45] method to generate dynamic community networks. They do this by defining a set of community events that can be used as seeds for the temporal evolution of the network. The subsequent snapshots of the graph are defined by this set of events.

Granell et al. [24] propose a model for generating simple dynamic networks based on stochastic block models (SBM). The time evolution consists of periodic oscillation of the system’s structure between configurations. Once the initial network is created, it is divided into subgraphs each having certain inter- and intra- connectivity probability. The edges between the timestamps are drawn from binomial distributions which themselves are modified by stochastic community-based events such as shrinking, growing, merging, and splitting.

Ghalebi et al. [20] similarly proposes an SBM model-based approach to generate dynamic community networks. Additionally, they propose a methodology to learn model parameters from existing real-world networks.

2.6.2 Real-world Datasets

Real-world network datasets are often categorized based on the source they model such as social networks, biological networks, and webpage networks. In Table 1 we present an overview of the most commonly used datasets in the literature. For each of the datasets, we describe their scale in terms of their node and edge counts. Additionally, we specify the presence of meta-topological information in the form of node types, whether the network is dynamic, whether it includes content-based (unstructured/textual) information, and the availability of node features.

Table 1. Summary of real-world datasets. Nodes column contains node counts and amount of node types within brackets to identify heterogeneous networks. Node attributes column indicates the presence of temporal data using character “T” and the presence of content-based (unstructured) data with character “C”.

Dataset	Source	Nodes	Edges	Node Attributes
Karate	[97]	34 (1)	78	-
Football	[22]	115 (1)	613	-
DBLP	[77; 93]	0.42M (4)	1.34M	33 (CT)

3 RESEARCH QUESTIONS

The main goal of my thesis is to build a framework for community detection and representation in dynamic heterogeneous networks.

This is, to enable dynamic community analysis on the datasets proposed in Wang et al. [80]. The data described is collected from the Twitter social platform and is dynamic, heterogeneous, and rich in content-based (unstructured text) data. To the best of our knowledge, there are currently no

dynamic community detection algorithms that can handle this data without relaxing its rich data representation (data loss).

As there are no alike algorithms, direct comparison is not possible. To both validate the merit of our methods as well as the quality of the results, we spread our research over four research questions.

RESEARCH QUESTION 1 (INFORMATION). Does addition of meta-topological and/or content-based information improve quality of detected communities?

While focusing on link-based features, CD algorithms treat all nodes alike. Therefore ignoring arguably most important structural features, namely node types. Additionally, supplementary node types can be constructed from categorical features enhancing network topology and solving issues requiring topic modeling.

Similarly, recent improvements in natural text processing allow for efficient representation of natural text which is proven to improve the quality of node embeddings. As the formation of communities is not purely a sociological process, the CD problem should benefit from the incorporation of such content-based features.

RESEARCH QUESTION 2 (SCALE). Does usage of graph representation function learning techniques improve scale of CD beyond current state-of-the-art?

The previously mentioned representation-based DCD method use spectral graph representation methods which operate on the whole network at once. More recent graph representation approaches instead learn a graph representation function by sampling the network using random walks or convolutions.

This has a two-fold positive effect on the scalability of the algorithms. Computation can be done more efficiently as opposed to spectral methods which rely on adjacency matrices. By learning a representation function, embeddings are computed on-demand instead of being held in memory for the whole network, therefore, limiting the impact of big networks. Other benefits may include the fact that they would be a suitable choice for processing streaming edge network variants.

RESEARCH QUESTION 3 (MODELLING). Does making temporal features implicit in node representations provide better quality communities as opposed to making them explicit?

Throughout the literature, various ways are used to incorporate temporal aspects into node embeddings. The implicit approach aims to make the embeddings temporally aware while the explicit approach creates a separate embedding for each snapshot. While methods using either approach have presented good results in the literature, it is important to analyze the potential trade-off and benefits of both.

RESEARCH QUESTION 4 (RESULTS). Do community-aware node embeddings perform well on both node as well as community evaluation based tasks?

While the main task of the algorithm is to find high-quality dynamic communities, the result also includes community-aware dynamic embeddings. Aside from testing the quality of the communities, it is important to compare how this community awareness influences the embeddings on dynamic node representation tasks such as link prediction and node classification.

4 APPROACH

To find an answer to our research questions, the methodology is split into multiple parts which address the selection of baselines, evaluation benchmark set up, the architecture of the algorithm, building an appropriate objective function, and elaborating on DCD result extraction respectively. While split, it is important to note that these tasks have a large overlap and won't be considered in isolation.

The final result of my thesis will consist of the said framework for DCD within dynamic heterogeneous graphs, a set of results comparing the algorithm to the current state-of-the-art approaches on various related tasks, and a set of ablation tests providing empirical corroboration for important design choices.

4.1 Benchmarks and Baselines

As the research questions posed in Section 3 are all mostly of a quantitative nature, it is very important to set up appropriate benchmarks in order to provide a valid answer. As a direct comparison between methods is not always possible, we define auxiliary task benchmarks testing algorithms on desired properties as well as reuse benchmarks used in previous literature to provide a fair comparison.

4.1.1 Benchmarks and Evaluation

To provide an answer for Research Question 1, the quality of the algorithm on both static and dynamic communities needs to be compared against the benchmarks for various configurations (considering the content and/or meta-topological data). As our baselines include both representation- as well as link-based approaches, the benchmarks should cover measures used in both groups. To evaluate the quality of the communities, annotation-based approaches (computing NMI and NF1) and quality metric-based evaluation approaches will be employed (See Section 2.5). Since our definition of community slightly differs from the literature as it encompasses network external information (content) we will also employ task-based evaluation such as recommendation tasks (follower recommendation, hashtag recommendation - depending on the dataset).

A similar evaluation methodology will be employed for Research Question 3, though the question is of a more exploratory nature concerning the modeling of temporal information, and therefore will be conducted as an ablation test with a focus on stability measures.

The Research Question 2 aims to compare the scalability of our approach to the current representation-based approaches. Therefore a rough complexity analysis, as well as performance benchmarking (computation time), shall be conducted.

Finally, Research Question 4 addresses the usability of our dynamic community detection results to other tasks concerning dynamic node representation learning. Here we, make use of defined auxiliary tasks (recommendation and link-prediction) to compare our method against more popular dynamic node representation learning algorithms.

4.1.2 Baselines

To give a fair representation of the state-of-the-art the following methods are selected as baselines. The selection is based on the category of communities they learn, diversification of techniques, and competitiveness with the ideas introduced as part of our framework.

Static Community Detection:

- Link-based:
 - He and Chen [32]
 - Rossetti [65]
- Representation-based:
 - Rozemberczki et al. [68]
 - Cavallari et al. [10]
 - Jia et al. [35]

Dynamic Community Detection:

- Link-based:
 - Rossetti [65]
- Representation-based:
 - Wang et al. [85]
 - Ma et al. [52]

Dynamic Representation Learning:

- Nguyen et al. [59]
- Wu et al. [88]

4.2 Representation learning

The core part of the proposed framework is the representation learning algorithm as it is responsible for both random walk sampling of the graph, as well as provides the architecture for the deep neural network used to learn or map the node representation. The representation learning can be split into three main components. Each of the components respectively has sufficient prior work and has been used in literature. The challenge lays in combining them into an efficient architecture for representation learning capable of maximizing set objective function.

4.2.1 Graph Sampling

The first component concerns efficient graph sampling, which is a way to enforce learning of desired topological properties from the network. Various ways to sample graphs can be found in the literature. For this work, the choice lies between random walk approaches [26, 26, 63] which traverse the graph in a depth-first search manner which is known for favoring homophily and convolution-based approaches (Kipf and Welling [40]; Hamilton et al. [30]) which sample the graph in a breadth-first search manner favoring structural equivalence. Both methods support heterogeneous graph sampling [18, 82, 89, 91, 96], and temporally aware sampling [15, 59, 88].

4.2.2 Neural Network Architecture

The architecture and training strategy of the underlying neural network matter. Many methods introduced in the previous section already outline an effective architecture suitable for training on the introduced sampling method. Because both data and requirements for our algorithms differ, they can't be used as is. The final architecture should allow for heterogeneous graph samples, temporal-aware samples, and node features.

Similarly, related literature can be used as inspiration as various approaches already utilize content-rich networks [89, 96], attention-based mechanisms [2, 70, 82], and alternative training strategies such (variational or diffusion) auto-encoders, GAN [38, 47].

4.2.3 Feature Fusion

Many of the presented datasets are feature-rich. While for some feature types using them is as simple as pre-processing the values and passing them to the DNN, some features require additional attention. The natural text features can be aggregated into a single representation vector using pre-trained embeddings [16, 62], and (large) categorical features may be transformed into network nodes, thus moving the information into topological domain [13, 87].

4.3 Objective Function

A very important part of representation-based DCD methods is the objective function. By utilizing node (and community) representation vectors one can optimize the network to maximize a multi-objective function using back-propagation. During the training process, the focus can be shifted between the different objectives. By focusing on defining necessary criteria for dynamic community detection which will give a rough overview of the multi-objective function we will use.

Cohesion. The most common definition states that communities are characterized by more dense inter-community connections compared to intra-community density. Representation methods extend this definition by noting that the density of the connections is can be represented by the topological similarity measure of two nodes. Clustering methods further extend this definition by defining similarity on multi-modal embeddings, therefore keeping the definition consistent for attributed networks. Therefore a viable choice for community cohesion would be the Silhouette Coefficient (See Section 2.5)

Homophily. To ensure reliable computation of the cohesion measure, the representation vectors need to be accurate. A way to train these representations is by assuming homophily which states that the more two nodes occur in the same context, the more similar they are. This is translated to network problems by using node neighborhood as context. Either using first-order proximity where nodes should occur in their counterpart's context or by utilizing second-order proximity where two nodes are similar if they share the same context. Hybrid approaches exist which optimize for both as they both model different semantics. This idea can also be extended to content-based features and attributed networks, therefore, extending the definition of a community through transitivity when the above definition for cohesion is utilized.

Temporal Smoothness. When talking about dynamic networks and communities, temporal smoothness should also be considered. Between subsequent timesteps, the dynamic networks often evolve, but not by a large amount. While individual nodes may change drastically within a single timestep, the communities are seen as more stable structures within the networks. Therefore the evolution of the communities should not exceed to global (network) or individual (node) evolution rate.

In most of the literature, this temporal smoothness is indirectly handled by result matching or reuse of results from previous timesteps. Within representation-based approaches, this property can be quantified and optimized for. A similar approach is employed to keep the embedding space temporally stable while only individual nodes may change.

4.4 Community Detection

As the final step of the framework, the viable dynamic communities need to be extracted. This may be done by simultaneously training community embeddings along with the node embeddings [49, 52, 85], therefore having the advantage that objective function can directly influence the resulting communities. Other approaches instead operate on the resulting embedding space or the augmented graphs to extract the resulting communities using link-based methods such as the

Louvain method or density-based clustering algorithms such as K-means, BIRCH [98], or OPTICS [3] yielding the benefit of losing the community count assumption.

In our approach, we plan to focus on direct community optimization, while avoiding hard-coding the model to specific assumptions using spectral clustering-based techniques and soft assignment clustering [48, 52].

4.5 Extensions

If the timing of the research project permits, while not the main focus of the research, additional extensions of the algorithms for future work may be explored. These extensions may encompass exploring evolutionary event detection within the extracted dynamic communities.

5 PLANNING

In this section, the approximate planning for my thesis is discussed. The research phase of the thesis is broken down into two-week blocks. Below a timeline of these sprints can be found along with goals expected to achieve by the end of the block. The final deadline for the thesis is June 13th, 2022.

5.1 Timeline

5.1.1 January 24 - 2 weeks

Preparing the datasets, and setting up benchmarks for the baseline methods. Implementation of baseline if the implementation is not publicly available.

5.1.2 February 5 - 2 weeks

Finishing up the benchmark implementation. Conducting the evaluation and collection of the results on the baselines for the RQ's.

5.1.3 February 19 - 2 weeks

Setting up graph sampling pipeline and experimentation with various representation-based approaches. Collecting performance results for ablation tests.

5.1.4 March 3 - 2 weeks

Experimenting and implementing incorporation of community-based objectives into the framework. Conducting experiments with temporal modeling for Research Question 3.

5.1.5 March 19 - 2 weeks

Finishing up experimenting and implementing incorporation of community-based objectives into the framework. Experimenting with community extraction and sub-sampling.

5.1.6 April 2 - 2 weeks

Evaluation and tuning of the algorithm parameters to collect results for Research Question 1 and Research Question 4

5.1.7 April 10 - 2 weeks

Evaluation and optimization of the algorithm for scalability. Collecting data for Research Question 2.

5.1.8 April 30 - 2 weeks

Writing thesis: describing the full methodology

5.1.9 May 14 - 2 weeks

Writing thesis: describing evaluation and summarizing the results

5.1.10 May 28 - 2 weeks

Completing the thesis and ensuring everything is ready for delivery.
